

Prostate cancer spreads to bones by overtaking the home of blood stem cells.

Next to skin cancer, prostate cancer is the second most commonly diagnosed cancer for men, and it is the second leading cause of cancer-related death in men. While the initial growth in the prostate is serious, a patient's prognosis worsens once the cancer has spread (metastasized) to other parts of the body. Researchers at Harvard University and the University of Michigan have discovered a key role of hematopoietic stem cells (HSC) in bone metastases, cancers that have spread into the skeletal system.

HSCs exist within a "niche" in bones. This is where they grow and differentiate into specialized cells. Researchers report that when prostate cancer metastasizes to the bone in a mouse model, it directly competes with healthy HSCs for the HSC niche.
