

Protein complex regulates transcriptional elongation, prevents tumor growth.

Printed from <https://www.cancerquest.org/newsroom/2011/03/protein-complex-regulates-transcriptional-elongation-prevents-tumor-growth> on 11/24/2024

The use of information stored in our genes is tightly controlled. The active use of a gene (called gene expression) involves the production of RNA based on the DNA code (transcription) into messenger RNA (mRNA). This mRNA is then 'read' and used to produce proteins via a four-step process called translation. Regulation of elongation, the third step in translation, can play a key role in controlling cancer development (tumorigenesis).

An international team of scientists has recently discovered that control of elongation is important in a process known as the epithelial-mesenchymal transition (EMT). EMT is a common feature of cancer cells during which they become less like normal adult tissues. EMT is directly correlated to tumor growth and metastasis. The TGF- β -activated-translational mRNP complex prevents tumorigenesis by inhibiting the translation of proteins that drive EMT. The researchers showed how this works by converting noninvasive breast epithelial cells into aggressive, metastatic cells.
