Most cancers are thought to arise because of changes that occur during the lifetime of the affected person. Some cancers have been linked to defective (mutant) genes that are inherited from the person's parent(s). The cancer itself is not inherited, but the defective genes make it more likely that particular cancers will occur. Families with these genes can have much more cancer than others.

The National Cancer Institute’s list of common cancer-related inherited genetic mutations includes mutations that affect several different tumor suppressor genes. The cancers caused by inherited changes to tumor suppressor genes include breast cancer, ovarian cancer, prostate cancer, leukemia, pancreatic cancer, and colon cancer.¹ ² ³

NOTE: Only a portion of each of these cancer types is linked to inherited mutations. The rest of the cases are called ‘sporadic’, and they are not hereditary.

Many cancers are now routinely tested to see if they are candidates for treatment with targeted drugs. This includes some of those linked to hereditary cancer syndromes and a growing list of other cancers.

Because the cancers on the list below can be due to inherited gene mutations, many people diagnosed with them chose to get tested to see if they have the gene of interest. ⁴ ⁵

Below are short descriptions of some of the better understood hereditary cancers:

Hereditary Breast Cancer
Li-Fraumeni syndrome
Cowden syndrome
Lynch syndrome
Familial Adenomatous Polyposis
Retinoblastoma
Multiple Endocrine Neoplasia
Von-Hippel Lindau Syndrome

Hereditary breast cancer and ovarian cancer

Genes: BRCA1, BRCA2
Related cancer types: Female breast and ovarian cancers, and other cancers, including prostate, pancreatic, and male breast cancer

BRCA1 and BRCA2 are tumor suppressor genes; their protein products are responsible for preventing uncontrolled cell division. Specifically, the BRCA1 and BRCA2 proteins are involved in repairing DNA damage and controlling other genes. The reason why mutations in these genes are specifically linked to breast and ovarian cancer is not completely clear, but it may be linked to the hormone estrogen. Breast and ovarian cells depend on the hormone estrogen to reproduce—and they respond to changing
levels of estrogen (levels of estrogen are affected by the menstrual cycle and puberty, for example). The rapid division caused by estrogen may lead to increased mutation in these genes and the subsequent development of cancer. 

**Li-Fraumeni syndrome**

*Gene:* TP53  
*Related cancer types:* Breast cancer, soft tissue sarcoma, osteosarcoma (bone cancer), leukemia, brain tumors, adrenocortical carcinoma (cancer of the adrenal glands), and other cancers.

The TP53 gene (also known as p53) codes for a very important tumor suppressor protein. It is involved in many activities that prevent cells from dividing uncontrollably. The important activities regulated by p53 include DNA repair, cell death (apoptosis), and control of the cell cycle. It is referred to as a “gatekeeper” gene, since its job is to ultimately protect the body from tumor formation. Inherited mutations in TP53 cause a person to be very susceptible to many kinds of cancers, since it is one of the body’s main defenses against cancer-causing activities.

**Cowden syndrome (PTEN hamartoma tumor syndrome)**

*Gene:* PTEN (phosphatase and tensin homolog)  
*Related cancer types:* Breast, thyroid, endometrial (uterine lining), and other cancers

PTEN is also a tumor suppressor gene. Like TP53, if PTEN is defective, cells may continue dividing, even though cancer-causing changes may be present. Specifically, the product of PTEN controls whether or not cells respond to messages telling them to either divide or undergo apoptosis (the cell version of suicide). If regulation of these messages is disabled, cells may end up dividing out of control, and a tumor may form. PTEN mutations are responsible for Cowden syndrome, which includes the formation of many hamartomas, which are non-malignant growths. Mutations also lead to an increased risk for breast cancer, thyroid cancer, and endometrial cancer (cancer of the uterine lining).

**Lynch syndrome (hereditary nonpolyposis colorectal cancer)**

*Genes:* MSH2, MLH1, MSH6, PMS2, EPCAM  
*Related cancer types:* Colorectal, endometrial, ovarian, renal pelvis, pancreatic, small intestine, liver and biliary tract, stomach, brain, and breast cancers

The genes involved in Lynch syndrome are DNA mismatch repair genes. The proteins encoded by these genes are responsible for correcting mistakes made when DNA is copied (DNA replication). When these genes are defective, the proteins cannot repair DNA properly. Often, the cancers associated with Lynch syndrome can be identified by ‘microsatellite instability’. Microsatellite is a term for a repeating sequence of DNA, such as CGCGCGCGG or TATATATAT. The human genome has many of these repeating sequences. Microsatellite instability means that the mutations specifically occur in these repeating sequences of DNA. Usually, there is a loss or gain of some repeats (i.e. CAGCAGCAG turns into CAGCAG). The changes in the repeated sequences can affect the stability of the DNA and can lead to cancer of many kinds.

**Familial adenomatous polyposis**

*Gene:* APC (adenomatous polyposis coli)  
*Related cancer types:* Colorectal cancer, tumors in the small intestine, brain, stomach, bone, skin, and other tissues. Also associated with non-cancerous (benign) growths (polps) of the colon and small intestine.

APC is a tumor suppressor gene that controls how often a cell divides, how cells stick to each other, and cell movement. APC is also involved in DNA damage detection and works with other proteins involved in cell-cell communication. Many different mutations in APC are known to cause familial adenomatous polyposis, a condition associated with the development of many, frequently hundreds, of polyps. It is very likely that at least one of the polyps will become cancerous at some time in the patient’s life. A defective APC protein can also cause desmoid tumors, which are thick benign tumors that arise from connective tissue.

**Retinoblastoma**

*Gene:* RB1 (retinoblastoma)  
*Related cancer types:* Eye cancer (cancer of the retina), pinealoma (cancer of the pineal gland), osteosarcoma, melanoma, and soft tissue sarcoma
The RB1 gene codes for the Rb protein, which is a tumor suppressor. Rb is responsible for halting cell division if conditions are not optimal (i.e., there is DNA damage that must be repaired, or the cell is stressed in some way). It has roles in controlling other proteins involved in DNA replication, apoptosis, and cell maturation (differentiation). When there is a mutation in the RB1 gene, the Rb protein may not work, so cell growth goes unregulated. For reasons that are not completely clear, changes to RB1 tend to cause cancer in the eye, specifically in the retina. When one mutated copy of the retinoblastoma gene is inherited (causing cancers known as germinal or familial retinoblastoma), the mutant gene is present in every cell in the body, leaving the person highly susceptible to other types of cancer, primarily the pineal gland, bones, soft tissue and skin.  

**Multiple endocrine neoplasia type 1 (Wermer syndrome)**

**Gene:** MEN1  
**Related cancer types:** Pancreatic endocrine tumors and (usually benign) parathyroid and pituitary gland tumors

MEN1 codes for a tumor suppressor protein called menin. The exact function of menin is unknown, but it appears to be involved in regulating cell division, DNA repair, and apoptosis. Over a thousand different mutations in the MEN1 gene are known to cause multiple endocrine neoplasia type 1. MEN type 1 involves tumor growth in endocrine glands (the glands in the body that produce hormones). The endocrine glands commonly affected by multiple endocrine neoplasia type 1 are the parathyroid gland, the pituitary gland, and the pancreas. Usually, a mutation in MEN1 leads to a shortened version of the menin protein, which is unstable and easily broken down. When this happens, one copy of the MEN1 gene does not produce a functioning menin protein. If a mutation arises in the second copy (which is common in endocrine glands, although the reason for this is unknown) the cell cannot produce any functional menin at all, which can lead to uncontrolled cell division and cancer.

**Multiple endocrine neoplasia type 2**

**Gene:** RET  
**Related cancer types:** Medullary thyroid cancer and pheochromocytoma (benign adrenal gland tumor)

The RET gene is a proto-oncogene that is involved in cell signaling. It spans the cell membrane, and acts as a receptor for signals that help cells respond to changes in their environment. MEN2 can be divided into three subtypes: MEN2A, MEN2B, and Familial Medullary Thyroid Carcinoma (FMTC). Most mutations in the RET gene that cause MEN2 are very small (point) mutations that change only one amino acid in the protein. Many of these mutations are associated with inherited (familial) medullary thyroid cancer.

**Von Hippel-Lindau syndrome**

**Gene:** VHL  
**Related cancer types:** Kidney cancer and multiple noncancerous tumors, including pheochromocytoma

The VHL gene works with other proteins to form the VCB-CUL2 complex. This complex causes other proteins in the cell to be broken down when they are damaged or no longer needed. One target of the VCB-CUL2 complex is hypoxia-inducible factor-2-alpha (HIF-2a). HIF-2a coordinates the body’s response to changes in oxygen levels by controlling cell division, and the formation of new blood vessels and red blood cells. When oxygen levels are normal, the VCB-CUL2 complex puts the brakes on HIF-2a. When VHL is mutated, the VCB-CUL2 complex cannot function properly, and can’t degrade HIF-2a or other proteins when they are damaged or not needed. HIF-2a may then stimulate excessive cell division and blood vessel formation, which leads to tumor and cyst formations, both characteristic of Von Hippel-Lindau syndrome.
